(Received 19 March 2019; published 17 June 2019)

We discuss the rotational cooling of diatomic molecules in a Bose-Einstein condensate (BEC) of ultracold atoms by emission of phonons with orbital angular momentum. Despite the superfluidity of the BEC there is no frictionless rotation for typical molecules since the dominant cooling occurs via emission of particle-like phonons. Only for macrodimers, whose size becomes comparable to or larger than the condensate healing length, a Landau-like, critical angular momentum exists below which phonon emission is suppressed. We find that the rotational relaxation of typical molecules is, in general, faster than the cooling of the linear motion of impurities in a BEC. This also leads to a finite lifetime of angulons, quasiparticles of rotating molecules coupled to phonons with orbital angular-momentum. We analyze the dynamics of rotational cooling for homonuclear diatomic molecules based on a quantum Boltzmann equation including single- and two-phonon scattering and discuss the effect of thermal phonons.

I. INTRODUCTION

The physics of a quantum impurity in collective many-body environments is an important subject of condensed matter physics. It dates back to the classic problem of a polaron put forward by Landau and Pekar [1] and Fröhlich and Holstein [2–5] to explain charge transport in solids resulting from the dressing of a moving electron with phonon-like excitations of the surrounding material. In many systems internal degrees of freedom of the impurity can be disregarded as their characteristic energy scale is well separated from that of the environment and the impurity can be treated as point-like object. The Fermi and Bose polarons recently realized in ultracold quantum gases [6–17] are important examples providing a many-body model system where impurity problems can be analyzed very precisely.

Also the dynamics of its formation can be studied, which is an equally important problem since collective properties such as the superfluidity of a BEC can strongly influence the equilibration dynamics [18–20]. Recently the concept of a polaron was extended to impurities with a more complex structure such as a molecule. It was shown that the coupling of rotation to collective excitations of a surrounding BEC can give rise to a new type of quasiparticles termed angulons [21–25]. In the present paper we discuss the cooling dynamics of the rotational degrees of freedom of a single, diatomic molecule immersed in a three-dimensional (3D) Bose-Einstein condensate, see Fig. 1, which is relevant both for the formation and the stability of angulons. To this end we use a microscopic quantum Boltzmann approach [26] based on a Bogoliubov theory of impurity-condensate interaction.

Emission and scattering of Bogoliubov phonons with orbital angular momentum off the molecule lead to a deceleration of the rotational motion and eventually to equilibration with the condensate.

For typical sizes of molecules and weakly interacting condensates there is no analog of a Landau critical velocity, i.e., there is, in general, no critical value of angular momentum below which phonon emission and scattering is suppressed. This is because the spatial structure of the molecule can only be resolved by high-energy phonons, which have a particle-like character. Thus different from the case of polarons, i.e., point-like impurities dressed with Bogoliubov phonons, there are in general no stable states of angulons. The rotational relaxation rates are, however, smaller than the typical binding energies of angulons.

The situation is different if one considers macrodimers, such as Rydberg molecules [27–30], where an atom is trapped in a high-lying Rydberg state of another atom. In this case molecular size and healing length can become comparable and the interaction with low-energy phonons becomes the most important one. The same holds true for impurities trapped in shallow, rotationally symmetric potentials. In this limit the superfluidity of the condensate changes the relaxation dynamics and we recover a Landau critical behavior. Below a certain angular momentum of the macrodimer the emission of phonons is effectively suppressed and the rotational relaxation stops in a prethermalized state.

The paper is organized as follows. In Sec. II we will introduce the model of a rigid rotor coupled to Bogoliubov phonons of an atomic BEC. The quantum Boltzmann equation used to describe the relaxation dynamics is reviewed in Sec. III and the different contributions to the relaxation rates resulting from spontaneous and thermal single- and two-phonon processes are derived. The relaxation dynamics of macromolecules will be discussed in Sec. IV and that of typical molecules in Sec. V.

II. MODEL

We here discuss the case of a diatomic molecule, which we describe as a rigid rotor of two point masses $m_1$ with distance $2r_0$, see Fig. 1, immersed in a three-dimensional
Scattering and exchange of angular momentum between excitations is a crucial process in the dynamics of atomic systems, particularly in weakly interacting Bose–Einstein condensates (BECs). This process involves the creation of phonons by interaction with condensate atoms, which in turn leads to the thermalization of angular momentum.

The inverse process requires the availability of thermal excitations, ensuring that the center of mass (COM) of the molecule is at rest in the laboratory frame of the BEC. When a diatomic molecule immersed into a BEC of density \( n_0 \) undergoes rotational relaxation by emission of phonons with orbital angular momentum and quantum numbers \( k, \lambda, \mu \), spontaneous creation of phonons by interaction with condensate atoms is possible. This process involves the interaction of the BEC with the molecule and leads to the scattering and exchange of angular momentum between the two atoms.

We assume that higher-order partial waves are not relevant for the scattering process with small rotational quantum numbers. This is because the modifications of the dispersion relation that have been discussed, e.g., for He-dimers in [23], apply uniquely to low-energy processes, and the interaction \( H_I(r) \) of a point-like impurity at position \( r \) with the BEC reads in terms of plane-wave Bogoliubov modes

\[
H_I(r) = \int \frac{d^3k}{(2\pi)^3/2} W_k e^{-ik \cdot r} (\hat{b}_k + \hat{b}_k^\dagger) + \frac{g_{\text{IB}}}{2(2\pi)^{3/2}} \int d^3k \int d^3k' W_{k,k'} \hat{b}_k^\dagger \hat{b}_{k'}^\dagger + \frac{1}{2} W_{k,k'} (\hat{b}_k \hat{b}_{k'}^\dagger + \hat{b}_{k'} \hat{b}_k^\dagger) e^{-i(k-k') \cdot r},
\]

where \( W_k = [k^2 \xi^2 / (2 + k^2 \xi^2)]^{1/4} = \sqrt{\epsilon_k / \omega_k} \) with \( \epsilon_k = k^2 / (2m_B) \) being the kinetic energy of the condensate atoms, and we used the abbreviations \( W_{k,k'}^\pm = W_{k,k'}^\pm W_{k,k'}^\dagger \). Making use of the decomposition of plane waves into spherical ones

\[
e^{ik \cdot r} = 4\pi \sum_{k,\mu} \hat{i}^2 j_{k}(r) Y_{\lambda,\mu}(\theta, \phi) Y_{\lambda,\mu}^*(\theta_k, \phi_k),
\]

we find that \( j_k(r) \) is the spherical Bessel function, and the orthogonality relations of spherical harmonics, such as \( \int d\Omega \hat{Y}_{\lambda,\mu}(\theta, \phi) \hat{Y}_{\lambda',\mu'}(\theta, \phi) = \delta_{\lambda,\lambda'} \delta_{\mu,\mu'} \delta_{\lambda,\lambda'}, \)

where \( \lambda = 0, 1, \ldots \) and \( \mu = -\lambda, -\lambda+1, \ldots, \lambda-1, \lambda \) are the quantum numbers of the orbital angular momentum of the phonons in the rest frame of the center-of-mass of the molecule. The spherical-mode operators fulfill bosonic commutation relations \( [\hat{b}_{k,\lambda,\mu}, \hat{b}_{k',\lambda',\mu'}^\dagger] = \delta(k-k') \delta_{\lambda,\lambda'} \delta_{\mu,\mu'} \). With this we find

\[
H_{\text{int}} = \sum_{k,\lambda,\mu} U_k(k) [Y_{\lambda,\mu}(\theta, \phi) \hat{b}_{k,\lambda,\mu} + Y_{\lambda,\mu}^*(\theta, \phi) \hat{b}_{k,\lambda,\mu}^\dagger] + \sum_{k' \neq k, \lambda', \mu'} U_{k,k',\lambda,\mu} [Y_{\lambda,\mu}(k) Y_{\lambda',\mu'}(k', \phi) \hat{b}_{k',\lambda',\mu} + Y_{\lambda',\mu'}^*(k, \phi) \hat{b}_{k',\lambda',\mu}^\dagger]
\]

where we made use of the fact that the distance of both atoms to the origin is the same and fixed to \( r = r_0 \).

The coupling constants for the single-phonon terms read

\[
U_k = \left\{ \begin{array}{ll}
g_{\text{IB}} \sqrt{\frac{\hbar}{\pi}} k W_k j_k(kr_0), & \lambda \text{ even}, \\
0, & \lambda \text{ odd},
\end{array} \right.
\]

with \( k = \sqrt{\frac{\hbar^2}{m_B} n_0^{1/3}} \).
and for the two-phonon terms

\[ U_{\lambda, \lambda'}^{j} = \begin{cases} \frac{2\text{Im} k k' j_{\lambda}(k r_{j}) j_{\lambda}(k' r_{j}) W_{\lambda, \lambda'},} & \lambda + \lambda' \text{even,} \\ 0, & \lambda + \lambda' \text{odd,} \end{cases} \]

(7)

The vanishing of the coupling constants for odd values of \( \lambda \) or \( \lambda + \lambda' \) is due to the inversion symmetry of the molecules. For the heteronuclear case also odd terms would be nonzero. As a consequence the symmetric molecule can only emit and absorb single phonons with even orbital angular momentum or phonon-pairs which have an even total angular momentum. Rotational cooling will thus occur in a cascade with angular momentum steps of two.

### III. QUANTUM BOLTZMANN EQUATION

We now want to study the dynamics of a molecular impurity with finite initial angular momentum interacting with the BEC, described by the Hamiltonian (5). The starting point is a master equation for the impurity-density matrix, \( \rho_{\mu}^{jn} \)

between angular momentum states which can be derived by integrating out the phonon degrees of freedom and employing a Born-Markov approximation. The Born approximation neglects higher-order scattering contributions and is valid for weak impurity-condensate interactions \( g_{\text{Im}} \). On a short time scale off-diagonal matrix elements dephase and it is sufficient to consider probabilities \( p_{jm} = \rho_{jm}^{jn} \)

only, for which we obtain a linear Boltzmann equation, with transition rates obeying Fermi’s golden rule \( \Gamma_{m \rightarrow n} = 2\pi \delta (E_{m} - E_{n}) |\langle m | H_{\text{Im}} | n \rangle|^{2} \)

[26]

\[
\frac{dp_{jm}}{dt} = \sum_{j'm'} (p_{jm'} \Gamma_{j'm' \rightarrow jm} - p_{jm} \Gamma_{jm \rightarrow j'm'}). \tag{8}
\]

In the following we will derive the transition rates resulting from single- and two-phonon processes.

#### A. Single-phonon transition rates

To determine the transition rates \( \Gamma_{jm \rightarrow j'm'} \) from Eq. (5), we make use of the matrix elements of spherical harmonics

\[
\langle j, m | Y_{\lambda \mu}(\theta, \phi) | j', m' \rangle = \frac{1}{\sqrt{4\pi}} G_{\lambda \mu}^{jm} \langle \lambda \mu | \lambda \mu \rangle,
\]

\[
G_{\lambda \mu}^{jm} = \sqrt{\frac{(2\lambda + 1)(2\mu + 1)}{(2j + 1)}} C_{jm, j'm'}^{\lambda \mu} C_{00,00} \phi
\]

where \( C_{jm, j'm'}^{\lambda \mu} \) are Clebsch-Gordan coefficients, which reflect angular momentum conservation.

As discussed in detail in the Appendix the spontaneous (sp) and thermal (T) contributions resulting from the single-phonon term in the interaction Hamiltonian read:

\[
\Gamma_{jm \rightarrow j'm'}^{\text{sp}} = \sum_{\lambda \mu} \gamma_{\lambda}^{j j'} G_{\lambda \mu}^{jm} G_{\lambda \mu}^{j'm'} \Theta_{j, j'}, \tag{9}
\]

\[
\Gamma_{jm \rightarrow j'm'}^{\text{T}} = \sum_{\lambda \mu} \gamma_{\lambda}^{j j'} G_{\lambda \mu}^{jm} G_{\lambda \mu}^{j'm'} \Theta_{j, j'}, \tag{10}
\]

\[
\Theta_{j, j'} = \Theta(j - j') \text{ is the heaviside step function and } \pi_{jj'} = (\exp[|E_{jj'}|/k_{B}T] - 1)^{-1} \text{ is the thermal phonon number corresponding to the transition energy } E_{jj'} = E_{j} - E_{j'} \text{ between rotational states with } E_{j} = j(j + 1)/m_{j} r_{j}^{2}. \text{ The effective transition rates for angular-momentum transfer } \gamma \text{ are given by}
\]

\[
\gamma_{\lambda}^{j j'} = \left\{ \begin{array}{ll}
\frac{\text{Im} k k' j_{\lambda}(k r_{j}) j_{\lambda}(k' r_{j})}{\sqrt{1 + 2\pi \gamma_{jj'}}} j_{\lambda}^{2}(r_{j} k_{j'}) & \lambda \text{ even,} \\
0, & \text{else,}
\end{array} \right.
\]

(11)

where \( k_{j'} \) is the phonon momentum corresponding to \( E_{jj'} \).

The discussion can be substantially simplified if we consider only the total probabilities for angular momentum \( j \), \( p_{j} = \sum_{m} p_{jm} \). Making use of the properties of Clebsch-Gordan coefficients we find that the total rates \( \sum_{m} \Gamma_{jm \rightarrow j'm'} = \Gamma_{j \rightarrow j'} \) are independent of \( m \) as expected from the rotational symmetry of the problem. Thus Eq. (8) simplifies to

\[
\frac{dp_{j}}{dt} = \sum_{j'} (p_{j'} \Gamma_{j' \rightarrow j} - p_{j} \Gamma_{j \rightarrow j'}) \tag{12}
\]

with the total rates

\[
\Gamma_{j \rightarrow j'}^{\text{sp}} = (2j + 1) \sum_{\lambda \mu} \gamma_{\lambda}^{j j'} (C_{\lambda \mu \lambda', \mu}^{00})^{2} \Theta_{j, j'},
\]

\[
\Gamma_{j \rightarrow j'}^{\text{T}} = (2j + 1) \sum_{\lambda \mu} \gamma_{\lambda}^{j j'} (C_{\lambda \mu \lambda', \mu}^{00})^{2} \pi_{jj'}. \tag{13}
\]

Since for the Clebsch-Gordan coefficients holds \( C_{\lambda \mu \lambda', \mu}^{00} = 0 \), if \( j' + j + \lambda \text{ is odd and } \gamma_{\lambda}^{j j'} = 0 \) for odd \( \lambda \), one recognizes that states with even (odd) initial angular momentum \( j \) can only decay into states with even (odd) final angular momentum \( j' \).

To get an impression of the dependence of the single-phonon decay rates on the angular momentum quantum numbers, we plotted in Fig. 2 the spontaneous scattering rates \( \Gamma_{j \rightarrow j'}^{\text{sp}} \) as functions of \( j \) and \( j' \) for two different values of \( r_{0}/\xi \). While for typical sizes of molecules, for which \( r_{0}/\xi \ll 1 \), shown in Fig. 2(a), there is a smooth dependence on \( j \) and \( j', \) one finds for macro-dimers, for which \( r_{0}/\xi \) is of the order of or larger than unity, shown in Fig. 2(b), that the decay rates are strongly suppressed for \( j \) below a critical value \( j_{c} \). Also the final angular momentum that can be reached in a single-phonon process is limited by a second critical value \( j_{c}' \). This will be discussed in more detail in Sec. IV.

#### B. Two-phonon transition rates

For the calculation of the two-phonon transition rates we need the matrix elements of the product of spherical harmonics

\[
\langle j'm' | Y_{\lambda \mu}(\theta, \phi) Y_{\lambda \mu}(\theta, \phi) | jm \rangle = \frac{1}{4\pi} \sum_{LM} G_{\lambda \mu \lambda', \mu}^{LM} G_{\lambda \mu \lambda', \mu}^{j'm'}
\]

(14)

As discussed in the Appendix and shown in Fig. 1 we find for the total transition rate corresponding to the scattering of a phonon off the molecule (\( \times \)) and the simultaneous excitation
of two phonons (\( \lambda = j \)), described by the two-phonon interaction terms in Eq. (5)

\[
\Gamma_{j \rightarrow j'}^\lambda = (2j' + 1) \sum_{\substack{L, \lambda', \lambda'' \in \{\pm 1\} \, \text{even} \, \text{or} \, \text{odd}}} \left( \frac{(2\lambda + 2\lambda')}{2L + 1} \right) \left( C_{j,0,0}^{\lambda,0} \right)^2 \left( C_{j',0,0}^{\lambda',0} \right)^2 \\
\times \int_0^\infty d\eta \gamma_{\lambda,\lambda';j \rightarrow j'}^\eta(\eta) \left[ \Pi_{j,\eta}(\eta) + \Theta_{j,j'} \right] \times \left[ \Pi_{j,j'}(\eta) + \Theta_{j',j} \right] \left( \eta k_{j,j'}(\eta) + \Theta_{j',j} \right],
\]

where \( \eta \) is a dimensionless scaling parameter, which characterizes how the energy of the transition is distributed over the two phonons, \( \Pi_{j,\eta}(\eta) \), and \( k_{j,j'}(\eta) \) are the thermal phonon and the phonon momentum corresponding to the scaled transition energy \( \eta E_{j,j'} \).

\[
\gamma_{\lambda,\lambda';j \rightarrow j'}^\eta(\eta) = \frac{g_{\text{in}}^2 |E_{j,j'}|^3}{2\pi \xi^4 \sqrt{1 + 2(\eta + 1)^2 E_{j,j'}^2 \xi^2 / c^2}} \\
\times \frac{j_{c}^2(r_0 k_{j,j'}(\eta)) j_{c}^2(r_0 k_{j,j'}(1 + \eta))}{\frac{\eta k_{j,j'}(\eta)}{\sqrt{1 + 2\eta E_{j,j'}^2 \xi^2 / c^2}}} \left( W_{j,j',j'}(\eta) k_{j,j'}(\eta+1) \right)^2.
\]

Since \( L \) is only summed over even numbers in Eqs. (15) and (16), the decay is still only possible from an initial state with even (odd) \( j \) to a final state with even (odd) \( j' \). So the two relaxation cascades remain separated also when considering two-phonon processes.

## IV. MACRO MOLECULES AND LANDAU CRITICAL ROTATION

As seen from Fig. 2 the single-phonon rotational relaxation is very different in the two cases of a usual molecule with \( r_0 \ll \xi \) and a macromolecule \( r_0 > \xi \) or an atom in a shallow rotationally symmetric trap. We thus will discuss these two cases separately in the following. We first consider macromolecules with a radius \( r_0 > \xi \), the opposite limit is discussed in a subsequent section.

### A. Relaxation rates and critical rotation

In the case of a macromolecule the spontaneous single-phonon decay rate \( \Gamma_{j \rightarrow j'}^{\text{sp}} \) is the dominating one at low temperature and is plotted in Fig. 2(b). The checkerboard pattern evolves as a consequence of the two independent relaxation cascades for even an odd angular quantum number.

As noted above, transition rates are suppressed for low angular momentum states and the molecule cannot decay to the lowest \( j \) value. This can be understood from analogy to linear motion of a single impurity through the condensate [19]. The impurity will not scatter phonons when its momentum is smaller than the Landau critical value \( p_c = m_c \xi \) and for large radii the rotation of the molecule can be approximated as a translation.

One can determine a critical angular momentum \( j_c \) below which the scattering of further phonons is strongly suppressed by simultaneous energy and angular momentum conservation. To this end we compare the energy of two linearly moving impurities, each with momentum \( p_c \), to one rotating molecule, identifying

\[
\frac{j_c(j_c + 1)}{4m_r r_0^2} = 2 \frac{p_c^2}{2m_i}.
\]

The corresponding Landau critical angular momentum \( j_c \) is then given by

\[
j_c(j_c + 1) = 2 \frac{m_c^2 \xi^2}{m_i \xi^2}.
\]

We note that to have an integer \( j_c \geq 1 \) the size of the molecule \( r_0 \) has, in general, to be larger than the healing length \( \xi \) or we need a very heavy impurity \( m_i > m_0 \).
Furthermore we know that a linearly moving impurity with \( m_1 > m_2 \) can only decay into a state with momentum bigger than \( p_j^{(1)} = p_c \sqrt{1 - m_2^2/m_1^2} \), when only single-phonon processes are considered. In analogy to the discussion above, one can derive the minimal angular momentum \( j_c^{(1)} \) a rotating macromolecule can decay into

\[
\frac{j_c^{(1)}}{j_c} + 1 = 2 \frac{\xi_0^2}{\xi^2} \left( \frac{m_2^2}{m_1^2} - 1 \right).
\]

Both \( j_c \) and \( j_c^{(1)} \) fit very well to the rates calculated for the Boltzmann equation, see Fig. 2(b).

To verify these estimates we look at the total spontaneous single-phonon decay rate \( \Gamma_{\text{1ph,sp}} \) of a molecule with angular momentum \( j \), which is given by

\[
\Gamma_{j^{\text{1ph,sp}}} = \sum_{j'} \Gamma_{j^{\text{1ph,sp}}}.
\]

In the inset of Fig. 3 \( \Gamma_{j^{\text{1ph,sp}}} \) is plotted for different ratios \( r_0/\xi > 1 \) against \( j \). One clearly notices a sharp onset at \( j_c \). The total rates reveal oscillations that arise from projection of different spherical harmonics and more strikingly, when plotting the decay rates as function of angular momenta normalized to the critical value from Eq. (20), all curves collapse to a single one when \( r_0 \gtrsim \xi \). This universal behavior can be understood in analogy to the case of two linearly moving impurities: For a rotating macromolecule with angular momentum \( j \gg 1 \) and rotational energy equal to the kinetic energy of two linearly moving impurities, each with momentum \( p \), one finds

\[
\frac{j}{j_c} = \frac{p}{p_c},
\]

independent on the ratio \( r_0/\xi \).

B. Cooling dynamics

Very similar to [19] one can show that the relaxation processes mediated by two-phonon processes are much slower than single-phonon terms in a weakly interacting 3D BEC, where \( n_0 \xi^3 \gg 1 \), since they scale as

\[
\Gamma_{2\text{ph}}/\Gamma_{1\text{ph}} \sim (n_0 \xi^3)^{-1}.
\]

Furthermore also thermally induced two-phonon processes are very slow and not relevant below \( T_c \). Note that the situation is markedly different in lower dimensions [20], where thermally induced processes can become important due to the infrared divergence of contributions by thermally occupied phonon modes.

Due to the existence of a Landau critical angular momentum we expect a prethermalization to a nonequilibrium rotational state, which is visible unless \( j_c \ll j_f \), which only happens at high temperatures. In Fig. 4 we plotted the time evolution of the occupation of angular momentum states starting at an eigenstate with \( j = 24 \). One clearly recognizes the formation of a prethermalized state with \( j \gg j_c^{(1)} \), while states with lower \( j \) will only be populated on a much larger time scales set by two-phonon processes.

We note that the mechanism of relaxation suppression discussed here is very different from that found in the opposite regime of rapidly rotating molecules in a thermal gas [32–35].

V. SMALL MOLECULES

A. Single-phonon rates and angulon stability

Typical molecules have sizes much less than the healing length of the BEC \( r_0 \ll \xi \). In this case we can drastically simplify the effective single-phonon transition rates (11) which yields

\[
\lambda^{j^j} = \begin{cases} \frac{\xi_0^2}{2 \pi \xi^2 m_0^2} \sqrt{\frac{m_0}{m}} \Delta_{j^j} \sqrt{\frac{m_0}{m}} \Delta_{j^j} \sqrt{\frac{m_0}{m}} \Delta_{j^j}, & \text{even}, \\ 0, & \text{else} \end{cases}
\]

where \( \Delta_{j^j} = |j(j+1) - j'(j'+1)| \).

Furthermore thermal contributions to the single-phonon rate can be completely disregarded as the energy spacing
The decay rates between adjacent rotational states is much larger than the thermal energy, $E_{j,j'/k_B T_c} > (m_B/m_l)(n_0^{1/3}r_0)^{-2}$. As a consequence $R_{j,j'} \ll 1$.

In Fig. 2(a), we plotted the transition rates $\Gamma_{j\to j'}^{\text{1ph,sp}}$ in the limit of a small molecule. An important difference to the case of a macromolecule is that the molecule always decays into the lowest angular momentum states $j = 0$ or 1.

The absence of a Landau critical rotation can be understood very simply from the following argument: Phonons can resolve the rotation of the molecule if their wavelength is comparable or smaller than the molecule size $r_0$. Thus the relaxation is dominated by scattering of high-energy, i.e., short wavelength phonons with $k \gg r_0^{-1} \gg \xi^{-1}$. These short-wavelength phonons are, however, particle-like and there is no suppression of their emission or scattering by simultaneous energy-momentum conservation. As a consequence quasiparticles arising from the dressing of rotating molecules with angular-momentum phonons are fundamentally unstable. Furthermore in the case of a linear motion of the impurity, it is known that the transition rates are on the order of $\Gamma_{\text{2ph}} \sim \xi^2 \gamma$. In contrast Eq. (25) shows that the typical transition rates for a rotating molecule are bigger by a factor $\xi/r_0$. This may raise concerns if angulons can be observed at all. However, the typical binding energies of angulons are sizable fractions of the rotational energy of the molecule. When we compare the single-phonon decay rate of angular-momentum states to the relevant energy scale, given by the rotational constant $B = \frac{1}{4m_r r_0^2}$, we find

$$\Gamma_{j\to j'}^{\text{1ph,sp}} B \propto r_0 \ll 1. \quad (26)$$

Additionally one recognizes from Fig. 3 that states with higher rotational number $j$ have a larger decay rate and therefore feature a broader spectral function. So while excited rotational states of a molecule in a BEC are not stable, their lifetime is still large compared to the energy of the angulon.

### B. Thermal two-phonon contributions

For single-phonon processes thermal effects can be neglected. This no longer holds true for processes involving two phonons. The dominant two-phonon process is the one, were the state of the molecule decays, via absorption of a low-energy thermal phonon and subsequent (spontaneous) emission of a high-energy phonon. For usually sized molecules, with $r_0 \ll r_0^{1/3} \ll 1$ the decay rates due to two-phonon processes are proportional to the spontaneous single phonon rates, with a proportionality factor which depends on the BEC temperature and $n_0 \xi^3$, but not on $j$ or $j'$. In Fig. 5 we plotted the ratio of thermal two-phonon to single-phonon decay rates from numerical calculations. One recognizes that they approach a universal curve (dashed line) when the gas parameter $n_0 \xi^3$ increases.

As shown in the Appendix one finds

$$\Gamma_{j\to j'}^{\text{2ph,T}} = \Gamma_{j\to j'}^{\text{1ph,sp}} \frac{\sqrt{2}}{4\pi^2 n_0 \xi^3} \int_0^\infty dk k \pi(k) \propto n_0 \xi^3 \int_0^\infty dk k \pi(k). \quad (27)$$

Here $\kappa$ is the energy of the thermal phonon in units of $c/\xi$, $k(\kappa)$ is the phonon momentum and $\pi(k)$ the thermal phonon number corresponding to this energy. For $n_0 \xi^3 \gg 1$ this expression can be further simplified which yields

$$\Gamma_{j\to j'}^{\text{2ph,T}} \sim \left( \frac{T}{T_c} \right)^{3/2} \Gamma_{j\to j'}^{\text{1ph,sp}}. \quad (28)$$

This simple relation holds since the thermal long-wavelength phonon absorbed in the two-phonon process carries effectively no angular momentum, and its energy is negligible compared to the transition energy $E_{j,j'}$. For a weakly interacting BEC the two processes, i.e., two-phonon scattering with absorption of a thermal phonon and single-phonon emission, only differ in that the impurity interacts with an initially condensed atom in one case and with a low-energy thermal atom in the other. Therefore the thermal contributions in the two-phonon scattering only lead to a renormalization of the single-phonon process, scaling with the thermal fraction. One recognizes, however, that at low temperature the two-phonon transition rates are still small compared to the single-phonon, so three or more-phonon processes are negligible. Furthermore direct three-body processes would not scale with the two-body interaction constant $g_{ab}$ but with the three-body interaction constant, which is substantially smaller than $g_{ab}$.

### C. Cooling dynamics

Finally we consider also the relaxation dynamics of small molecules. To this end we solve the Boltzmann equation (8) numerically by calculating the spontaneous decay rates (13) and their thermal equivalent (10). To include two-phonon processes given in Eqs. (15) and (16) we focus on a subset of momenta up to $j \leq 25$. Figure 6 shows the angular momentum decay of an initial state with $j = 24$ into a final state with $j = 0$. For small molecules the influence of two-phonon processes increases slightly, but they do not lead to qualitative changes other than a small modification of the single-phonon contribution as per Eq. (28). We observe a smooth and fast
The authors would like to thank Richard Schmidt, Mikhail Lemeshko, and Artur Widera for fruitful discussions. The work was supported by the German Science Foundation (DFG) within SFB TR49, Programs No. 31867626, No. SFB TR185, and No. 277625399.

ACKNOWLEDGMENTS

To calculate the single-phonon transition rates Eqs. (9) and (10) we first evaluate the matrix element in $\Gamma_{j_m \to j_n} = 2\pi \delta(E_{\text{in}} - E_{\text{out}})|\langle m|H_{\text{int}}|n\rangle|^2$, which yields

$$
\Gamma_{j_m \to j_n}^{\text{ph}, \text{sp}} = \frac{1}{2} \sum_{k, \lambda, \mu} \delta(E_j - E_{j'} - \omega_k) U_j(k) G_{j_m, \lambda, \mu}^{j_m, \lambda, \mu},
$$

(A1)

and

$$
\Gamma_{j_m \to j_n}^{\text{ph}, \text{th}} = \frac{1}{2} \sum_{k, \lambda, \mu} U_j(k) \sum_{\lambda'} G_{j_m, \lambda', \mu}^{j_m, \lambda', \mu} \delta(E_j - E_{j'} - \omega_k).
$$

(A2)

We made the assumption that the phonon number $\bar{n}_{k,j'}$ depends only on $k$, which is valid for thermal phonons. The integration over the absolute value of the phonon momentum $k$ can be carried out. Furthermore by using the symmetry $G_{j_m, \lambda, \mu}^{j_m, \lambda, \mu} = G_{j_m, \lambda', \mu}^{j_m, \lambda', \mu}$ the thermal transition rates can be simplified. This yields

$$
\Gamma_{j_m \to j_n}^{\text{ph}, \text{th}} = \frac{1}{2} \sum_{k, \lambda, \mu} \frac{dk_{\omega}}{d\omega} U_j(k) \sum_{\lambda'} G_{j_m, \lambda', \mu}^{j_m, \lambda', \mu} |_{\omega = \omega_{j'j}},
$$

(A3)

and

$$
\Gamma_{j_m \to j_n}^{\text{ph}, \text{th}} = \frac{1}{2} \sum_{k, \lambda, \mu} \frac{dk_{\omega}}{d\omega} U_j(k) \sum_{\lambda'} \bar{n}_{k,j'} G_{j_m, \lambda', \mu}^{j_m, \lambda', \mu} |_{\omega = \omega_{j'j}},
$$

(A4)

where $k_{\omega} = \frac{1}{\sqrt{1 + 2\omega^2 E_j^2/c^2} - 1}$ is the inverse of the dispersion relation $\omega_{j'j}$. The effective single phonon transition rates Eq. (11) are then defined as

$$
\Gamma_{j'j}^{\omega} = \frac{1}{2} \frac{dk_{\omega}}{d\omega} U_j(k) \sum_{\lambda'} G_{j_m, \lambda', \mu}^{j_m, \lambda', \mu} |_{\omega = \omega_{j'j}}.
$$

(A5)

The derivation of the two-phonon rates can be done in a similar way. In the following the term proportional to $U_{j'j}^{\omega}(k, k')$ will be considered. The derivation of the rates proportional to $U_{j'j}^{\omega}(k, k')$ follows analogously. When evaluating the matrix element of $H_{\text{int}}$ proportional to $U_{j'j}^{\omega}(k, k')$ one finds

$$
\Gamma_{j'j}^{\omega}(k, k') = \frac{1}{8\pi} \sum_{\lambda, \mu} \sum_{k, k'} U_{j'j}^{\omega}(k, k')^2 \bar{n}_{k,j'} \delta(E_j - E_{j'} - \omega_k + \omega_k) \times \sum_{\lambda''} G_{j_m, \lambda'', \mu}^{j_m, \lambda'', \mu} G_{j_m, \lambda', \mu}^{j_m, \lambda', \mu} G_{j_m, \lambda', \mu}^{j_m, \lambda', \mu} G_{j_m, \lambda', \mu}^{j_m, \lambda', \mu}.
$$

(A6)

what is already summed over all final $m$. For the $D$s can be simplified using properties of the

FIG. 6. Time evolution of angular momentum of a microdimer starting at $\rho_{j_0} = 1$. The color encoding matches the occupation number $\rho_{j}(t)$ plotted on the $z$ axis. For long times $t$ we find a pumping to the final state with $j = 0$. Here we have $\rho_0 = 0.1\xi$ and $m_l = 2m_0$ and a finite temperature $T = 0.01T_c$.
Clebsch-Gordan coefficients \[36\]
\[
\sum_{LL,MM'}^{\mu L'} G_{\mu L',\mu L}^{LL} G_{\mu L',\mu L}^{MM'} G_{\mu L',\mu L}^{LM'} G_{\mu L',\mu L}^{MM'} = (2j' + 1) \sum_{L} \frac{(2j' + 1)}{2L + 1} C_{\mu L,\mu L}^{LL} C_{\mu L,\mu L}^{MM'} \tag{7}\]
Furthermore the integral over \(k'\) can directly be carried out and the one over \(k\) is transformed into an integral over \(\eta\), where \(\eta E/J\) is the energy corresponding to the momentum \(k\). This yields Eq. (15), where the effective transition rate is given by
\[
y_{\eta;j',j}^{\mu L,j';j} = \frac{|E_{jj'}|}{8\pi} \frac{dk_{\eta}}{d\omega} \bigg|_{\eta = \eta E/J} \frac{dk_{\eta}}{d\omega} \bigg|_{\eta = \eta (1 + \eta E/J)} \times [U_{\mu L,j}(k_{\eta}(\eta), k_{\eta}(\eta + 1))]^2. \tag{8}\]
When a typical size molecule should be described this can be simplified further. In the following the essential steps to derive Eq. (27), which gives the ratio between rates due to two- to single-phonon processes, are explained. Since \(E_{jj'} \gg \hbar \Omega\), the molecule cannot be excited, so \(j > j'\). This yields
\[
\Gamma_{f \rightarrow j} \propto \int_{0}^{\infty} d\eta \eta y_{\eta;j',j}^{\mu L,j';j}(\eta) \bar{\eta}_{j',j}(\eta)|\bar{\eta}_{j,j}(\eta + 1)|. \tag{9}\]
The thermal phonon \(\bar{\eta}_{j',j}(\eta)\) number at energy \(\eta E/J\) decays exponentially with \(\eta\). So only \(\eta \ll 1\) must be considered in the integral, which is valid for \(\eta \sqrt{\hbar \Omega} \ll 1\). This has the physical meaning that the energy of the thermal absorbed phonon can be neglected when compared to the energy of the emitted one. In this approximation the wavelength of the thermal phonon is much bigger than the molecule, so \(\hbar k_{\eta}(\eta) \ll 1\) which leads to
\[
j_{\eta}(\hbar k_{\eta}(\eta))^2 \approx \delta_{\lambda,0}. \tag{10}\]
Since all spherical Bessel function \(j_{\lambda}(x)\) with \(\lambda > 0\) are vanishing for small \(x\), this leads to the conclusion, that the thermal absorbed phonon carries no angular momentum.
